### **Abstract**

**Background:** Colorectal cancer (CRC) continues to be a worldwide health problem with early detection being used as a key component in mitigating deaths due to the disease. Previous research suggests a link between fecal bacterial microbiome and CRC. The overall objective of our study was to investigate the changes in the bacterial microbiome after surgery in patients with lesion (i.e. adenoma or carcinoma). Specifically, we wanted to identify what within the community was different within those undergoing surgical removal of lesion. We also wanted to investigate the use of the bacterial microbiome and Fecal Immunoglobulin Test (FIT) to build models which could classify individuals as having a lesion or as before surgery. **Results:** Adenoma individual's bacterial microbiome were more similar to their pre-surgery 11 sample then those with carcinoma (P-value = 0.00198). Their change in FIT was also significantly different then those with carcinoma (P-value = 2.15e-05). There was no significant difference in any indivdiual OTU between samples before and after surgery (P-value > 0.125). A model with a total of 37 variables was able to classify lesion (AUC = 0.847 - 0.791) while the model to classify samples as before surgery had 33 variables (AUC = 0.79 - 0.651). The after surgery samples had a significant decrease in the model positive probability of a lesion or before surgery sample (P-value = 1.91e-11 and 6.72e-12). In total there were 14 OTUs that were common to both models and the majority of these classified to commensal bacteria (Bacteroides, Blautia, Streptococcus, and Clostridiales). Conclusions: Our data suggests that treatment not only significantly reduces the 21 probability of having a colonic lesion within our models but also causes detectable changes in the bacterial microbiome. Further surveillance of these individuals will enable us to determine whether models such as the ones we present could be used to predict

recurrence of colorectal cancer.

<sup>27</sup> bacterial microbiome; colorectal cancer; polyps; FIT; detection; risk factors

### 28 Background

Colorectal cancer (CRC) continues to be a leading cause of cancer related deaths and is the second most common cancer death among men aged 40-79 years of age [1,2].

Over the last few years death due to the disease has seen a significant decrease, thanks mainly to improvements in screening [1]. However, despite this improvement there are still approximately 50,000 deaths from the disease a year [2]. It is estimated that around 5-10% of all CRCs can be explained by autosomal dominant inheritance [3]. The vast majority of CRCs are not inherited and the exact etiology of the disease has not been well worked out [2]. Although many risk factors have been identified [2] and non-invasive screening techniques have started to be put into consistent use [4,5] there has been an additional increase in the incidence of CRC in the younger population.

This increased incidence of CRC in the younger population is concerning since having
either an adenoma or carcinoma increases ones risk for future adenomas or carcinomas
[6–8]. This increased risk can also carry with it an increased chance of mortality due to
this recurrence [9,10]. Therefore, there has been a great amount of interest in early risk
stratification tools [11,12] that can help identify those that may be at most susceptibility
to reccurence. Concurrently, there has also been a lot of interest in new areas that could
have a role in disease pathogenesis, such as the gut bacterial microbiome.

There has been promising work on the bacterial microbiome and it's ability to be able to complement existing screening methods such as Fecal Immunoglobulin Test (FIT) or act alone as a screening tool [13,14]. There has also been research into how this microbiome could be altered directly on tumor tissue itself [15]. A few studies have now even shown how this microbiome [16] or specific members within it [17] could be directly involved with the pathogenesis of CRC. These studies have helped to provide a tantilzing link between the bacterial microbiome and CRC. However, at this present time there remains limited

- information on the bacterial microbiome before and after successful surgery for removal of the adenoma or carcinoma and whether it changes at all.
- In this study we investigated what happened to the bacterial microbiome before and after surgery for indivdiuals with either adenoma or carcinoma. Our anlaysis includes both alpha and beta diversity analysis along with investigation of individual operational taxonomic units (OTUs). We also utilized Random Forest models and observed how these models as well as specific OTUs within them performed before (initial) and after (follow up) surgery. We also used these models to look for similar important OTUs to identify the crucial OTUs for not only classifying initial and follow up samples but also lesion or normal.

### 2 Results

Bacterial Community and FIT Based on the thetayc distance metric, comparing the initial to the follow up samples, there was a significant difference between the adenoma and carcinoma groups (P-value = 0.00198) [Figure 1a]. There was also a significant 65 difference in change in FIT between initial and follow up samples (P-value = 2.15e-05) 66 [Figure 1b]. The whole community structure before and after surgery was visualized on 67 NMDS graphs for both adenoma [Figure1c] (PERMANOVA = 0.997) and carcinoma [Figure 1d] (PERMANOVA = 0.002). When all initial and follow up samples were compared to each 69 other there was no significant overall difference between them (PERMANOVA = 0.085). There was no significant difference between initial and follow up samples for observed 71 OTUs, Shannon diversity, or evenness after correction for multiple comparisons [Table S1]. There was also no significant difference between initial and follow up samples for any single OTU [Figure S1].

Previously Associated Cancer Bacteria We next examined whether there were differences in previously well described carcinoma associated OTUs. These included the OTUs that aligned with Porphyromonas asaccharolytica (Otu000153), Fusobacterium nucleatum (Otu000226), Parvimonas micra (Otu000460), and Peptostreptococcus stomatis (Otu000653). First, the carcinoma samples showed a significant difference between initial and follow up samples for Peptostreptococcus stomatis (P-value = 0.0183) and Porphyromonas asaccharolytica (P-value = 0.0154) whereas there were no significant differences in any of these OTUs in the adenoma samples [Table S4]. Second, when these OTUs were present, there was a clear magnitude difference based on whether they were from adenoma or carcinoma [Figure 2]. However, only a small percentage of those with adenoma or carcinoma were positive for any of these OTUs.

Full and Reduced Model Since differences were observed between initial and follow up

samples and only a small number of individuals were positive for previously associated CRC bacteria; we next investigated if we could create models that could adequately classify and adjust either lesion or before sample probability based on the bacterial community and FIT. The lesion model had an AUC range of 0.723 to 0.795 versus the before sample model which had an AUC range of 0.451 to 0.67 after 100 iterations of 20 repeated 10-fold cross validations. Interestingly, identification of the most important variables and reducing the models to only these factors increased the AUC in the lesion model (0.791 - 0.847) and before sample model (0.651 - 0.79).

The test set AUC range for the full and reduced lesion model were similar to that reported for the training set AUC ranges and the ROC curve ranges overlap each other [Figure 3a]. The ROC curve for the final lesion model used was within the range of both the full and reduced lesion model [Figure 3a]. Interestingly, the test set AUC range for the before sample model performed much better then the training set AUCs. Both the full and reduced before sample models overlapped with each other [Figure 3b] there was a marked decrease in the ROC curve for the final model used.

Most Important Variables The reduced models were built based on the most important variables to the respective full model. For the lesion model there were a total of 37 variables [Figure S2] whereas for the before sample model there were a total of 33 variables [Figure S3]. For both models FIT resulted in the largest decrease in MDA [Figure S2a & S3a].

Positive Probability after Lesion Removal Regardless of model used there was a significant decrease in the positive probability of either the sample being lesion or a before sample on follow up [Figure 4 & S4] (full lesion P-value = 1.11e-11, reduced lesion P-value = 1.91e-11, initial and follow up P-value = 6.71e-12, and reduced initial and follow up P-value = 6.72e-12).

For the full and reduced lesion model there was a significant difference in the classification

for the lesion model between predicted and actual (P-value = 4.19e-10 and 6.98e-10, respectively) but not for the before sample model (P-value = 1.00 and 1.00). However, the lesion model correctly kept the one individual who still had a carcinoma on follow up above the cut off threshold [Figure 4a & S4a] for a positive call while the before sample models did not [Figure 4b & S4b].

Common OTUs to both Models There were a total of 14 OTUs that were common to both models. Of these OTUs the most common taxonomic identifications were to Blautia, Bacteroides, Streptococcus, and Clostridiales. The majority of these OTUs had classifications to bacteria typically thought of as commensal [Table S2].

Treatment and Time Differences There was no difference in the amount of change in positive probability for either the full or reduced lesion model for either chemotherapy (P-value = 0.821 and 0.821) or radiation therapy (P-value = 0.69 and 0.981). Although the before sample model was similar there was a significant decrease in positive probability for those treated with chemotherapy (P-value = 7.04e-04 and 5.07e-03). Time elapsed between the collection of the follow up sample from the initial sample, did not have a significant difference between adenoma and carcinoma (uncorrected P-value = 0.784).

### 28 Discussion

146

150

151

There was no difference in alpha diversity metrics between the initial and follow up samples [Table S1]. Yet based on thetayc there was a significant difference between inital and 130 follow up samples [Figure 1a] with carcinoma samples being more dissimilar to their 131 initial samples then adenoma samples. The change in FIT was also different between 132 initial and follow up for those with adenoma or carcinoma [Figure 1b]. There was also a 133 significant difference in the overall bacterial community structure for those in the carcinoma 134 group [Figure 1d] before and after surgery but not for the adenoma group [Figure 1c]. 135 Investigation of the OTU relative abundance before and after surgery found no single OTU 136 to be significantly different [Figure S1]. 137

Interestingly, when only previously associated cancer bacteria were investigated only 2
out of the 4 had a significant decrease in relative abundance between initial and follow
up for the carcinoma group and 0 out of the 4 were significant for the adenoma group.
This data suggests that the changes that may be important in the bacterial microbiome
after surgery are not necessarily any one specific bacterium, a clear depression of CRC
related bacteria, nor any addition of new or depressed bacterium but rather that a shift of
the bacterial community as a whole occurs with the existing members of this microbiome.

We next created a model that incorporated FIT and the bacterial microbiome to either be able to classify lesions (adenoma or carcinoma) or initial and follow up samples in order to confirm that the community was what was responding or changing due to surgery. We found that the OTUs that made up the most important variables to the model overwhelmingly belonged to comensal bacteria. With only the lesion model having a single OTU from previously associated cancer bacteria (*Porphyromonas asaccharolytica*). Using only these important OTUs and FIT both models (lesion and initial and follow up) had a significantly decreased positive probability of either lesion or being an initial sample on follow up

[Figure 4 & S4]. Confirming the importance of the changes of comensal bacteria to these classifications was that a total of 14 OTUs were common to both models and the vast majority belonged to regular residents of our gut community.

There was no difference for the majority of models tested for differences in positive probablity based on whether chemotherapy or radiation was received. There was also no difference in the thetayc distance metric based on length of time between initial and follow up sample between adenoma and carcinoma. These results would indicate that the findings described were specific to the surgical intervention and that differences observed between carcinoma and adenoma samples can not be simply attributed to collection time between samples.

This study builds upon previous work from numerous labs that have looked into the bacterial 163 microbiome as a potential screening tool [13,14] by exploring what happens to the bacterial 164 community after surgical removal of a lesion. Based on previous work by Arthur, et al. 165 [18] it may not be surprising to have E.coli as one of the most important OTUs and one 166 that was common to both models. Interestingly, many of the most important OTUs had 167 taxonomic identification for resident gut microbes. This could suggest that the bacterial community is one of the first components that could change during the pathogenesis of 169 disease. These bacterial microbiome changes could be the first step in allowing more inflammatory bacterium to gain a foothold within the colon [19]. 171

Curiously, we observed that the typical CRC associated bacteria were not predictive within our models. One potential explanation is that even with surgery and a shift of the bacterial community these specific bacteria still persisted within the colon. An alternative reason would be that even if they were reduced in relative abundance they were still present. Another potential explanation is that they were not present in enough individuals to be able to classify those with and without disease with a high degree of accuracy. It is possible that our Random Forest models were able to get the same information from measures such as

FIT or other OTUs. Finally, it is also possible that all three of these potential explanations could have played a role. Regardless, our observations would suggest that an individual's 180 resident bacteria have a large role to play in disease initiation and could change in a way 181 that allows predictive models to lower the positive probability of a lesion after surgery 182 [Figure 4]. It should be stated that our study does not argue against the importance of 183 these CRC associated bacteria in the pathogenesis of disease but rather that the models 184 do not utilize these specific bacteria for classification purposes (lesion or initial and follow 185 up). In fact, it is possible that these CRC associated bacteria are important in the transition 186 from adenoma to carcinoma and would be one explanation as to why in our data we not 187 only see high initial relative abundances, in certain individuals, but also large decreases in 188 relative abundance in those with carcinoma but not in those with adenoma after surgery 189 [Figure 2].

One limitation of our study is that we do not know whether individuals who were still classified as positive by the lesion model eventually had a subsequent CRC diagnosis. 192 This information would help to strengthen the case for our Random Forest based model 193 to have kept a number of individuals above the cutoff threshold even though at follow up 194 they were diagnosed as no longer having a lesion. Another limitation is that we do not 195 know if adding modern tests such as the fecal DNA test [20] could help improve our overall 196 AUC. Another limitation is that this study drew heavily from those with caucasian ancestry. 197 The results may not be immediately representative of those with either Asian or African 198 ancestry. Finally, although our training and test set are relatively large we still run the 199 risk of overfitting or having a model that may not be immediately extrapolateable to other 200 populations. We've done our best to safeguard against this by not only running 10-fold 201 cross validation but also having over 100 different 80/20 splits to try and mimic the type of 202 variation that might be expected to occur. 203

Another interesting outcome was that Within figure 3 the initial and follow up model showed

better test AUC results then the training set AUC. This may have occured because the training AUC that was determined from 20 repeated 10 fold cross validation removed samples at random and did not take into account that they were matched samples. Another potential reason is that the model itself may be overfit since the total number of samples was not that large. However, the lesion model did not suffer from these discrepencies and 209 similar conclusions can be drawn solely from this model. Regardless, further independent 210 studies will need to be carried out to verify our findings since not only are we dealing with feces, which could be very different than the communities present on the actual tissue, but 212 also are dealing with correlations that may not be representative of the true pathogensis of 213 disease.

207

208

211

Despite these limitations we think that these findings significantly add to the existing scientific knowledge on CRC and the bacterial microbiome. The ability for machine learning algorithms to take bacterial microbiome data and successfully lower positive probability after either adenoma or carcinoma removal provides evidence that there are specific signatures, mostly attributable to commensal organisms, associated with these 219 lesions. It also shows that these algorithms can not only successfully react to successful 220 treatment regimens but also may be able to one day stratify CRC disease risk with a high 221 level of accuracy. 222

### Methods

Study Design and Patient Sampling The sampling and design of the study was similar to that reported in Baxter, et al [13]. In brief, study exclusion involved those who had already undergone surgery, radiation, or chemotherapy, had colorectal cancer before a 226 baseline fecal sample could be obtained, had IBD, a known hereditary non-polyposis 227 colorectal cancer, or Familial adenomatous polyposis. Samples used to build the models 228 for prediction were collected either prior to a colonoscopy or between 1 - 2 weeks after. The 229 bacterial microbiome has been shown to nomralize within this time period [21]. Our follow 230 up data set had a total of 67 individuals that not only had a sample as described previoulsy 231 but also a follow up sample between 188 - 546 days after surgery and treatment had been 232 completed. This study was approved by the University of Michigan Institutional Review 233 Board. All study participants provided informed consent and the study itself conformed to 234 the guidelines set out by the Helsinki Declaration. 235

FIT and 16S rRNA Gene Sequencing FIT was analyzed as previously published using
both OC FIT-CHEK and OC-Auto Micro 80 automated system (Polymedco Inc.) [22]. 16S
rRNA gene sequencing was completed as previously described by Kozich, et al. [23]. In
brief, DNA extraction used the 96 well Soil DNA isolation kit (MO BIO Laboratories) and
an epMotion 5075 automated pipetting system (Eppendorf). The V4 variable region was
amplified and the resulting product was split between three sequencing runs with control,
adenoma, and carcinoma evenly represented on each run. Each group was randomly
assigned to avoid biases based on sample collection location.

Sequence Processing The mothur software package (v1.37.5) was used to process the 16S rRNA gene sequences. This process has been previously described [23]. The general processing workflow using mothur was as follows: Paired-end reads were first merged into contigs, quality filtered, aligned to the SILVA database, screened for chimeras,

classified with a naive Bayesian classifier using the Ribosomal Database Project (RDP), and clustered into Operational Taxonomic Units (OTUs) using a 97% similarity cutoff with an average neighbor clustering algorithm. The numer of sequences for each sample was rarified to 10521 in an attempt to minimize uneven sampling.

**Lesion Model Creation** The Random Forest [24] algorithm was used to create the model used for prediction of lesion (adenoma or carcinoma) with the main testing and training 253 of the model completed on a data set of 490 individuals. This model was then applied to 254 our follow up data set of 67 individuals. The model included data on FIT and the bacterial 255 microbiome. Non-binary data was checked for near zero variance. Data columns that 256 had near zero variance were removed. This pre-processing was performed with the R package caret (v6.0.73). Optimization of the mtry hyperparameter involved taking the samples and making 100 80/20 (train/test) splits in the data where control and lesion were equally represented in the 80 and 20 split, respectively. This 80% portion was then split again into an 80/20 split, and run through 20 repeated 10-fold cross validations to optimzie 261 the model's AUC (Area Under the Curve of the Receiver Operator Characteristic). This 262 resulting model was then tested on the 20% of the data that was originally held out from 263 this overall process. Once the ideal mtry was found the entire 490 sample set was used 264 to create the final Random Forest model on which testing on the 67-person cohort was 265 completed. The default cutoff of 0.5 was used as the threshold to classify individuals as 266 positive or negative for lesion. The hyperparameter, mtry, defines the number of variables 267 to investigate at each split before a new division of the data is created. 268

Initial Follow Up Model Creation We also investigated whether a model could be created that could identify before and after surgery samples. The main difference was that only the 67-person cohort follow up data set was used at all stages of model building and classification. Other than this difference the creation of this model and optimization of the mtry hyperparameter was completed using the same procedure that was used to create

274 the lesion model.

Selection of Important OTUs In order to assess which variables were most important to all the models we counted the number of times a variable was present in the top 10% of mean decrease in accuracy (MDA) for each different 80/20 split model and then filtered this list to variables that were only present more than 50% of the time. This final collated list of variables was what was considered the most important for the lesion or initial follow up models.

Statistical Analysis The R software package (v3.3.2) was used for all statisitical analysis.

Comparisons between bacterial community structure utilized PERMANOVA [25] in the

vegan package (v2.4.1). Comparisons between probabilities as well as overall OTU

differences between initial and follow up samples utilized a paired wilcoxson ranked sum

test. Where multiple comparison testing was needed a Benjamini-Hochberg (BH) correction

was applied [26] and a corrected P-value of less than 0.05 was considered significant.

Unless otherwise stated the P-values reported are those of that were BH corrected.

Analysis Overview Initial and follow up samples were analyzed for differences in alpha and beta diversity. Next, differences in FIT between initial and follow ups for either 289 adenoma or carcinoma were investigated. From here, all OTUs that were used in the 290 lesion model were then analyzed using a paired wilcoxson test. We then investigated 29 the relative abundance of specific previously CRC associated bacteria, specifically, 292 OTUs that taxonomically classified to Fusobacterium nucleatum, Parvimonas micra, 293 Peptostreptococcus assacharolytica, and Porphyromonas stomatis. We wanted to test if 294 there were any differences based on whether the individual had an adenoma or carcinoma. 295 From here the lesion model was then tested for accuracy in prediction and whether it 296 reduced the positive probability of lesion after surgery. The most important OTUs for this 297 were used to build a reduced model and it was assessed for similarity to the original model. 298 We then used the initial follow up model to assess whether it could classify samples better

then the lesion model. The most important OTUs were then identified from this model and used to create a reduced feature initial follow up model. This reduced feature model, as was done with the lesion model, was compared to the full model for loss of accuracy. Finally, a list of common OTUs were found for the two different models used.
